A Reconfigurable Reflectarray Antenna With an 8 \( \mu \text{m} \)-Thick Layer of Liquid Crystal

Weiquan Zhang\(^\circledR\), Yue Li\(^\circledR\), Senior Member, IEEE, and Zhijun Zhang\(^\circledR\), Fellow, IEEE

Abstract—This article demonstrates an electronically scanned reflectarray antenna based on liquid crystal (LC). The LC-based reflectarray element was designed as a periodically loading of parallel H-shaped polygons on two metal layers. To realize a tunable reflection phase and reduce the inhomogeneity effect of LC, an 8 \( \mu \text{m} \)-thick LC layer was designed as a varactor rather than a substrate. In simulations, the adjustable reflection-phase range of the proposed element was 180° in the frequency band 21–21.5 GHz. The design concept was verified on a reflectarray prototype containing 26 rows of the basic elements. In addition, a 32-channel control circuit was designed and fabricated for biasing. The measured results confirmed a tunable phase range of 150° at 23.8 GHz. The disagreements between the simulated and measured results are discussed, and a test process is proposed. As a proof of concept, the main beam was steered to 0°, −40°, and −60° in one plane. The result confirmed the high beam-steering capability of the proposed reflectarray antenna with measured gains above 18 dB at 23.8 GHz. This work provides useful references for the design and measurement of LC-based reflectarray antennas.

Index Terms—Beam scanning reflectarray, liquid crystal (LC), liquid crystal display (LCD) technology, response speed.

I. INTRODUCTION

R E F L E C T A R R Y antennas have gained considerable interest owing to their low cost, ease of construction, and ability to electronically reconfigure the beam [1]. Reflectarray antennas also enable beam scanning, so they are widely used in satellite communication, radar, and imaging applications. The phase shift function of each element is the key problem in reflectarray antennas. The beam can be reconfigured using control devices or tunable materials. Suitable control devices are varactor diodes [2], [3], p-i-n diodes [4], [5], and the microelectromechanical systems switch [6]–[8], which alter the physical structure or resonant frequencies of the elements. The parasitic effect of diodes is nonnegligible in frequency bands above 10 GHz. Alternatively, the reflection phase can be changed by employing tunable materials, such as barium strontium titanate [9], ferrite [10], and liquid crystal (LC) [11]–[13]. As a low-cost and easily integrated material, LC is suitable for microwave-range applications, especially at frequencies higher than the Ku-band [14], [15]. Applying a changing quasi-static electric field to an LC material with alterable permittivity value can realize a reconfigurable antenna. In [16]–[19], transmission lines with LC substrate were employed as phase shifts. In [18], the feed phase of a patch array was tuned through an inverted microstrip line loaded with a 254 \( \mu \text{m} \)-thick LC substrate. Such phase-shifter structures are simple and intuitive but not easily integrable into systems. To change the resonant frequency of an antenna or its elements, some researchers have applied LC materials as the substrate of the working elements [18], [20]–[26]. Hu et al. [24] proposed an electronically tunable bandpass filter with a frequency-selective surface [24] consisting of a 130 \( \mu \text{m} \)-thick LC layer. In [26], a 510 \( \mu \text{m} \)-thick LC substrate enabled changeable resonant frequencies of a microstrip patch antenna. The LC-based reflectarray is an attractive option for microwave and millimeter-wave applications [14]. Several designs and investigations of LC-based reflectarrays can be found in the literature [12], [13], [23], [27]–[33]. Perez-Palomino et al. [12] achieved a wideband reflectarray at 100 GHz employing a multiresonant element with an 80 \( \mu \text{m} \)-thick LC. A phase-agile microstrip reflectarray with a 15 \( \mu \text{m} \)-thick LC layer enables operation at frequencies above 100 GHz [13]. A 35-GHz reconfigurable microstrip reflectarray utilized a highly anisotropic LC with a thickness of 127 \( \mu \text{m} \) [23]. Meanwhile, the modern LC filling process of an LC-display mass-production line limits the size of LC cells to several microns. In a more practical and low-cost LC-based reflectarray, the LC thickness should be less than 10 \( \mu \text{m} \). A thinner LC layer is also expected to raise the switching speed. Therefore, developing an LC-based reflectarray with fast response speed remains a major challenge.

This article proposes a reconfigurable reflectarray with an 8 \( \mu \text{m} \)-thick LC. The reflectarray is designed, fabricated, and tested at 23.8 GHz. To realize a reconfigurable array, the 8 \( \mu \text{m} \)-thick LC material was designed as a varactor. The reflection phase of the proposed element is insensitive to the incident angle. A reconfigurable reflectarray composed of 26 × 38 identical LC-based elements was fabricated and tested. A microcontroller for driving the LC material was also designed and fabricated. The 32-channel microcontroller generates square-wave pulses with an ac voltage range from 0 to 11 V at 277 Hz. The proposed reconfigurable reflectarray antenna has a single-plane beam scanning capability from −60° to 60°.
The 2-D scanning capability can be achieved by using a 1-D phased array as the feed.

The main contribution of this work is summarized as follows.

1) A new reconfigurable reflectarray with a thin (8 μm) LC layer is designed and fabricated. The thin LC layer improves the switching speed of the array. The proposed antenna is compatible with current LC display technology.

2) The LC material is deployed as a varactor rather than as a substrate for changing the reflection phase.

3) This work provides useful references for the design and measurement of reflectarray antennas based on continuously adjustable materials.

The remainder of this article is organized as follows. Section II presents and discusses the reflectarray element and its operating mechanism. Section III is devoted to the fabrication and performance measurements of the antenna. The work is summarized in Section IV.

II. ANTENNA DESIGN

A. Reflectarray Element

The permittivity of LC can be altered by changing the applied quasi-static field. For this reason, LC material is frequently exploited in the design of reconfigurable reflectarray antennas [12], [13], [23], [27]–[32]. In most of the published works, the LC material is utilized as the substrate for changing the resonant frequency of the element. In [12] and [31], an LC-based substrate achieved tunable resonant frequency of a dipole element. Similarly, patch elements loaded with LC substrates have realized variable reflection phases [13], [28]–[30], [32]. The effects of LC anisotropy and inhomogeneity on the reflection phase have also been reported [34], [35]. Increasing the contributing volume of LC was found to enhance the effects of anisotropy and inhomogeneity. Usually, the impacts of anisotropy and inhomogeneity of LC cannot be ignored when loading LC as the substrate. This article proposes an element based on periodically loaded parallel H-shaped polygons with an 8 μm-thick LC and a small effectively biased region. In this design, different incident-wave angles and the LC inhomogeneity exert limited effects, as discussed next.

The proposed LC-based antenna cell is depicted in Fig. 1. The cell contains two substrates, three metal layers, and one LC layer. The LC material fills the cavity formed by the two substrates. A ground plane is loaded on the bottom layer of the lower substrate. An H-shaped polygon is periodically printed on the top and bottom surfaces of the lower and upper substrates, respectively [see Fig. 1(b)]. Two overlapping square areas exist between the adjacent H-shaped polygons in the +Z-direction (overlapping area II). The top and bottom copper layers are interconnected by the top and bottom bias lines, respectively. The two biased lines overlap in the +Z-direction (overlapping area I). For convenience, we refer to the LC regions between the two biasing lines and the LC regions between the overlapping square area (overlapping areas I and II, respectively) as LC-I and LC-II, respectively. LC-I and LC-II are collectively called LC-III. A quasi-static electric field is generated by the bias lines. The dielectric constant of LC-III can be tuned by changing the bias voltage. The varying permittivity of LC-I under different bias voltages negligibly affects the reflection phase of the reflectarray. This phenomenon will be explained later. The LC material is manufactured by BOE (Beijing, China), and its specification parameters (given by BOE) are $\varepsilon_{//} \approx 3.6$, $\varepsilon_{\perp} \approx 2.6$, and $\tan \delta < 0.01$. The substrate is glass with a relative permittivity of $\varepsilon_r \approx 5.2$ and a loss tangent $< 0.01$. Table I gives the detailed dimensions of the reflectarray cell. In the present simulations, the maximum and minimum permittivities of LC were selected as 2.65 ($\varepsilon_{\perp}$) and 3.6 ($\varepsilon_{//}$), respectively.

As the reflectarray is biased by rows [see Fig. 2(a)], the beams can steer only in one plane. The simulated reflection phases and reflection losses of the cell with periodic boundaries and different permittivities are depicted in Fig. 2(b). Changing the permittivity of LC-III from 2.65 to 3.6 induces a $180^\circ$ phase shift with reflection losses of less than 2.5 dB in the 21.0–21.5 GHz range. The radiation performance can be improved by increasing the reflection-phase range [36]. In future work, the phase shift range can be enlarged by using multiresonant elements.

To reveal the operation principle of the reflectarray, the reflectarray cell was investigated in working mode. Fig. 3(a) plots the simulated current distribution in the cell under a normally incident X-polarized plane wave at 21 GHz. Part of the structure is enlarged to clarify the imagery. Half-wavelength loop modes were excited on both sides of the bias lines. Fig. 3(b) depicts the simulated E-field distribution on the YZ plane, where AA’ denotes the reference line. The electric field intensity is strong between the overlapping areas I and weak between overlapping areas I. Foreseeably, the LC-II works as a varactor that changed the resonant frequency of the loop mode. The altered LC-I’s permittivity little affects the reflection phase. This concept was verified in two simulations. Fig. 3(c) plots the reflection phases as functions of the frequency with different $\varepsilon_r$ values of the LC-II and LC-III regions. The simulated results with identical $\varepsilon_r$ values of LC-II and LC-III agree well with each other, and changing the permittivity of LC-I negligibly affects the simulated reflection phase [see Fig. 3(d)]. Therefore, the influence of the permittivity of LC-I on the phase shift can be ignored.

Next, the sensitivity of the reflection phase to incident angle was investigated by varying the incident angle of illumination on the proposed cell. Fig. 4 compares the frequency responses of the reflection phase in LCs with different $\varepsilon_r$’s at two incidence angles: $\theta = 0^\circ$ and $\theta = 45^\circ$. Here, $\theta$ is defined as the angle between $k$ and the +Z-axis in the XZ plane. Relative to the reflection phases at $\theta = 0^\circ$, the reflection phases at $\theta = 45^\circ$ deviate by $-10^\circ$, $6^\circ$, and $14^\circ$ with...

Fig. 4. Simulated frequency responses of the reflection phases of the LC-based cells with different relative permittivities, illuminated by an X-polarized plane wave at different incident angles ϑ.

Fig. 5. Schematic of the control circuit.

Both = 2.65, 3.125, and 3.6, respectively, at 21 GHz. Similar results were obtained at 21.5 GHz, confirming the negligible effect of oblique incidence.

B. Control Circuit

Each element of an LC-based reflectarray can be biased by square pulses generated by a microcontroller. Fig. 5 shows a schematic of the control circuit. All bottom bias lines are gathered to provide the signal ground. Each of the top bias lines is connected from the glass to the flexible printed circuit (FPC). The microcontroller was designed to generate square waves with continuous ac voltage for biasing. The input is controlled by a microprogrammed control unit (MCU). The digital inputs from the MCU are transformed to analog signals by D–A converters. The appropriate voltage range can be obtained using operational amplifiers (OPAs). The MCU and laptop are linked by an USB to a transistor–transistor logic converter. Hence, the bias status of each element can be easily controlled by changing the input value on the PC.

C. Fabrication

Fig. 6(a) shows the manufactured reflectarray with 26 rows of basic elements. Each row contains 38 basic cells, as shown in Fig. 1(a). All the top bias lines are connected to the FPC. The fabrication technology is similar to normal LC display technology. In this work, the reflectarray was fed by a series-fed microstrip antenna, which was fabricated, as shown in Fig. 6(b). The reflectarray and feed antenna are fixed on plastic support fabricated using 3-D printing technology [see Fig. 6(c)]. The feed is placed directly above the reflectarray at a height of 49 mm. The feed is parallel to the element.

Fig. 7 shows the control circuit fabricated with printed circuit board technology. The control circuit includes one MCU (STM8L101g3u6), four DAs (R2A20168NP), and eight OPAs (ST LF347). The output of the control circuit was connected to the FPC of the reflectarray through an FPC connector (FH28-40S-0.5SH). A 277 Hz square wave with a bias voltage range of 0–11 V was generated by the control circuit.

III. EXPERIMENTAL VERIFICATION

A. Measurement Setup

Fig. 8 depicts the measurement setup of the experimental verification. The control circuit was driven by a direct voltage supplied by a dual dc power supply (LPS 202A). The bias voltage of each bias line was controlled by a laptop connected...
to the control circuit by a USB-to-TTL converter (HW-597). The fabricated series-fed microstrip antenna worked as a transmitter (Tx), while a rectangular waveguide worked as a receiver (Rx). The received signal was amplified by a low-noise amplifier (LNA). Measurements were performed in an anechoic chamber.

### B. Reflection Phase Test

To measure the reflection phase of the fabricated reflectarray, the Rx was tilted to receive the reflection wave, as shown in Fig. 9(a). Recall that the reflection phase of the proposed antenna is insensitive to the incident angle and is mainly determined by $\varepsilon_r$ of the LC. The phase of $S_{Rx,Tx}$ is affected by the reflection from the partial area of the reflectarray. Predictably, the phase of $S_{Rx,Tx}$ can characterize (to some extent) the change in the reflection phase of the LC-based reflectarray with different $\varepsilon_r$'s. This observation was demonstrated in a simulation. Two rectangular waveguides were used as the Tx and Rx [see Fig. 9(b)]. The simulated reflections for different $\varepsilon_r$'s at 21.5 GHz were normalized, and the relative phase shift was approximately 180°. The simulated results demonstrate the effectiveness of the test method. When the same bias voltage (0–11 V) was applied to all rows during the measurement process, the phase of the receiving signal changed with different bias status. Fig. 9(c) depicts the tuning capability of the reflectarray at 23.8 GHz. The antenna generated an approximate relative phase shift of 150° at 23.8 GHz. The simulated operating frequency and the relative phase shift were 21.5 GHz and 180°, respectively. The
discrepancy between the simulated and measured results was mainly caused by fabrication errors.

The proposed antenna was fabricated similar to traditional LC displays, but the Cu deposition process differed and was rendered difficult by the relatively low working frequency in this study. A part of the fabrication process is shown in Fig. 10. Considering the skin effect in the microwave band, the Cu layer must be approximately 1.5 μm thick. As the Cu deposition process is not sufficiently mature to deposit 1 μm-thick coating, the real thickness of the Cu layer varied from 1.5 to 3.8 μm ($h_3$). A layer of glue was then attached to the surface. Because the Cu layer was thicker than 1 μm, the glue height was increased near the Cu. Spacers were obtained by eroding the unneeded parts of the glue. A height error $h_4$ caused by protuberance occurred in spacers near the Cu layer. The total fabrication error of the LC thickness (provided by BOE) was ~40%. Considering the nonnegligible fabrication error, the change of the operating frequency of the reflectarray was deemed reasonable. To demonstrate that the disagreement between the simulated and measured results was caused by the thickness error, we investigated the height of the LC layer ($h_5$) in the simulation. The working frequency was higher, and the relative phase shift range was smaller in the modified case than in the original case. The relative phase shift was approximately 150° near 23.5 GHz, consistent with the measured results.

**C. Measurement of Radiation Patterns**

Based on the measured relative phase shifts of the reflectarray, a test process was proposed, as shown in Fig. 12. First, the required compensation phase of each row element can be

obtained from the reflectarray parameters, the height of the feed, and the considered scanning direction. Second, the bias voltage of each element is calculated based on the measured relative phase shift. The bias voltage can be varied by selecting different phase centers of the measured results. Third, the radiation patterns are measured in an antenna near-field test. If the measured gains around the desired direction are not improved, the phase center should be reselected. The fourth step finds the position of the desired radiation direction in the far-field. Fifth, the bias voltage of each row is fine-tuned to improve the gain (measured $S_{21}$) in the desired direction. The final measured patterns are then obtained in a near-field test.

Applying the above process, far-field measurements at 23.8 GHz were obtained in an anechoic chamber. Fig. 13 plots the measured results of the realized reflectarray for three main-beam directions: 0°, −40°, and −60°. The results were optimized using the calculated bias voltages. The final results (fine-tuned results) were obtained by fine-tuning the calculated bias voltage of each bias line. The corresponding bias voltages of the optimized and fine-tuned results are listed in Table II. The discrepancy in the bias voltages of the optimized and fine-tuned results was mainly caused by fabrication error. As shown in Fig. 13, the gain in the desired direction was higher in the fine-tuned results than in the optimized results, thereby validating the test process. The measured gain of the feed at 23.8 GHz was 15.5 dB. The final measured gains of the antenna oriented at 0°, −40°, and −60° were 18.1, 18.4, and 18.9 dB, respectively. The broadside gain was limited by the blocking effect of the feed and support. The high sidelobe level presented in Fig. 13(b) and (c) was mainly caused by phase quantization error [36]. The steering ability of the proposed reflectarray is not limited to the abovementioned directions. In fact, the main beam can be continuously steered to wide angles by virtue of the continuously adjustable capabilities of LC. In summary, the main lobes were successfully steered to the desired directions through the optimization routine.

Table III summarizes the electrical performances of this work and other LC-based reflectarray antennas. The proposed antenna has a thinner LC layer and a wider scanning range than the other antennas. The LC material was employed as a varactor in this work; in the previous studies, it was employed as the substrate for tuning the reflection phase.

IV. CONCLUSION

This article investigated a reconfigurable LC-based reflectarray. The antenna element is constructed by periodically loading H-shaped polygons. An 8 μm-thick LC layer is loaded as a varactor. In the simulation study, the basic element achieved a relative phase shift of 180°. A reflectarray with 26 rows of the basic element was then fabricated and tested. The refractarray was illuminated under a series-fed microstrip antenna, and a 32-channel control circuit was designed for biasing. The
disagreements between the measured and simulated results were studied and discussed. The antenna patterns in the desired main-beam directions were measured at 23.8 GHz through the proposed test process. The beam steering capability in one plane of the reflectarray was validated at different steering directions of the main beam (0°, −40°, and −60°). Scanning in another plane can be achieved by designing a 1-D phase array as the feed. The proposed design scheme offers a new solution to the design and measurement of LC-based reflectarray antennas.

ACKNOWLEDGMENT

The authors thank BOE for manufacturing the liquid crystal (LC) panels and providing technical support. They are also grateful to Mr. T. Ting and Mrs. C. Tang of BOE for fruitful discussions.
